afibrinogenemia, dysfibrinogenemia, fibrinogen, genetic mutation

ABSTRACT
Congenital qualitative and quantitative fibrinogen disorders represent heterogeneous rare abnormalities caused by mutations in one of the 3 genes encoding individual fibrinogen polypeptide chains, located on chromosome 4q28. It is estimated that congenital fibrinogen disorder accounts for 8% of rare coagulation factor deficiencies. Most of congenital fibrinogen disorders are suspected in individuals with bleeding tendency or coincidentally discovered, for instance prior to surgery. Fibrinogen disorders could be also found in patients with thrombotic events, impaired wound healing, and recurrent spontaneous abortions. Afibrinogenemia manifests as mild to severe bleeding, while hypofibrinogenemia is often asymptomatic. Dysfibrinogenemia, a qualitative fibrinogen disorder, is associated with bleeding, thrombosis, or with no symptoms. Recent recommendations issued by the International Society on Thrombosis and Haemostasis in 2018 do not encourage routine evaluation of thrombin time or other coagulation tests in patients with suspected congenital fibrinogen disorders, highlighting the value of fibrinogen antigen measurement and genetic analysis, added to the key finding, that is, reduced fibrinogen concentration determined with a coagulometric assay. The current review summarizes practical issues in diagnostic workup and clinical management of patients with afibrinogenemia, hypofibrinogenemia, dysfibrinogenemia, and hypodysfibrinogenemia from a perspective of internists who may encounter patients with reduced fibrinogen concentration in everyday practice. Despite the fact that hematologists are in front line for the management of patients with bleeding tendency, internists should be aware of the clinical and laboratory findings in patients with inherited fibrinogen disorders including the risk of thromboembolism and management prior to invasive procedures.

Fibrinogen structure  Fibrinogen is a 340 kDa protein synthesized in the liver.¹ Its normal concentration in blood plasma is in the range of 1.5 to 4.0 g/l. The half-life of circulating fibrinogen is about 3 to 4 days. The fibrinogen molecule is a hexamer, made up of 3 pairs of homologous Aα, Bβ, and γ polypeptide chains connected by disulfide bridges that form a central E region composed by the N-terminal portions of all 6 chains and 2 terminal D regions containing the C-terminal fragments of the Bβ and γ chains.¹ The C-terminal fragments of the Aα chains form globular structures located near the central E region.¹ After cleavage of fibrinopeptides A and B mediated by thrombin, fibrin monomers are formed, which polymerize through the interaction of the D region with the E regions of subsequent monomers to form protofibrils and through their lateral aggregation, thick fibrin fibers are crosslinked in a reaction catalyzed by thrombin-activated factor XIII.³ Fibrin, together with platelets and red blood cells, provide structural integrity to the hemostatic plug under physiological conditions and to the growing thrombus in thrombotic disorders. The final fibrin clot has a highly heterogeneous structure, determined by genetic and, to a much larger extent, environmental factors, which results in a large interindividual variability of clot architecture, thickness of fibers, and their branching.² Lower fibrinogen concentrations are known to result in the formation of thicker fibrin fibers creating looser meshwork which is more susceptible to fibrinolysis and mechanical fragmentation, eventually leading to an increased risk of bleeding. On the other hand, irregular abnormal
structure of fibrin, even at lower fibrinogen concentrations, could paradoxically increase thrombotic risk by impairing fibrin degradation by plasmin or facilitating clot fragmentation.2,3

Congenital fibrinogen disorders Genetic background
Congenital disorders of fibrinogen is a heterogeneous group of rare abnormalities most often caused by mutations in one of the 3 separate genes encoding individual polypeptide chains, located on chromosome 4q28 in a cluster of about 50 kbp (FGA, FGB, and FGG, respectively, for chains Aα, Bβ, and γ, but the order of genes from centromere to telomer is as follows: FGG, FGA, and FGO).4 So far, over 450 mutations in FGA, FGB, and FGG genes have been registered, of which over 250 are symptomatic (www.geht.org). The most common mutations (50%–80%) are single-amino acid missense mutations. Other defects responsible for fibrinogen abnormalities include nonsense mutations, read frame changes through small deletions or insertions in the coding part of the gene (frameshift), splicing-site mutations, and large deletions.5 Less than 5% of cases are genetic variants located in the 3’ and 5’ untranslated regions of the genes.5 Still, a few patients with severe fibrinogen deficiency have no identified genetic cause, and the use of next-generation sequencing can help clarify genetic background of these disorders.

The causative mutations described so far result in either qualitative or quantitative fibrinogen disorders.5 Quantitative disorders are traditionally divided into afibrinogenemia (complete absence of fibrinogen) and hypofibrinogenemia (proportionally reduced functional fibrinogen and its antigen levels).4,5 Afibrinogenemia is inherited in an autosomal recessive manner, while hypofibrinogenemia, dysfibrinogenemia, and hypodysfibrinogenemia are autosomal dominant.4 Afibrinogenemia is due to homozygosity or compound heterozygosity of a null mutation.4 It is estimated that quantitative congenital fibrinogen disorder accounts for 8% of rare coagulation factor deficiencies.9 The prevalence of afibrinogenemia is estimated to be 1/1 000 000 or more in some countries where marriage of close relatives is common, for example, in Iran.4 As hypofibrinogenemias are mainly caused by heterozygosity for fibrinogen gene mutation, they are much more frequent than afibrinogenemia.

Qualitative fibrinogen disorders include dysfibrinogenemia (normal amount of dysfunctional fibrinogen) and hypodysfibrinogenemia (decreased amount of dysfunctional fibrinogen). Almost all dysfibrinogenemias are caused by heterozygous missense mutations in FGA and FGG genes. Their prevalence is unknown as they are often asymptomatic.6 In a recent systematic analysis of exome/genome data from about 140 000 individuals of genome databases, it was estimated that their prevalence is up to 0.3% to 1%.1 Two hotspot mutations are particularly frequent, one affecting residue Arg35 in exon 2 of FGA and other affecting Arg301 in exon 8 of FGG. The mechanisms underlying clinical manifestations observed in qualitative congenital fibrinogen disorders involve abnormal formation of a fibrin clot associated with disturbed release of fibrinopeptides, delayed fibrin polymerization or defective cross-linking.4,8,9 A single mutation altering a fibrinogen chain may result in significant changes in the tertiary and quaternary structure of the protein causing all of the above disorders.4,5,9 To date, about 30 different mutations causing hypodysfibrinogenemia have been identified (10 in the FGA gene, 5 in the FGB gene, and 15 in the FGG gene). Most of these fibrinogen mutations were inherited in an autosomal dominant manner.10 Combined heterozygosity was found in additional 7 patients with hypodysfibrinogenemia.10 In patients with hypodysfibrinogenemia, the hypofibrinogenemic phenotype results from mutation affecting synthesis, assembly, and secretion or leading to an increased fibrinogen clearance, while the dysfibrinogenemic phenotype results from impaired fibrin polymerization and abnormal binding of calcium ions or tissue plasminogen activator.10

The first Polish case of dysfibrinogenemia, Fibrinogen Kraków associated with the Asn325Ile mutation in the fibrinogen γ chain and causing hypodysfibrinogenemia with thrombotic manifestation, was described in 2009.11 Genetically characterized fibrinogens described for the first time in Polish patients are shown in Table 1 (for the whole report, see Wypasek et al).17

Clinical manifestations In patients with afibrinogenemia, umbilical stump bleeding in newborns is the typical first manifestation of the disease, observed in 85% of cases.13 Bleeding in afibrinogenemia may also commonly occur as nosebleeds and less frequently cutaneous bleeding, gastrointestinal hemorrhage, and genitourinary bleeding. Intracranial bleeding, often spontaneous, is the most common cause of death in patients with afibrinogenemia.12 Intramuscular and hemorrhagic also occur in afibrinogenemia, usually less currently and less damaging than in severe hemophilia, even though severe arthropathies have also been reported in afibrinogenemia.9 Three additional manifestations are considered specific for afibrinogenemia, namely spontaneous spleen rupture, impaired wound healing, and the formation of painful bone cysts.14 Afibrinogenemia in women is typically associated with spontaneous miscarriages in the first trimester of pregnancy.13 Other pregnancy-related manifestations include pre- or postpartum hemorrhages, as well as placental abruption. Indeed, fibrinogen ensures placental integrity and is necessary for the development of blood vessels in its villi.13 Over 50% of women with afibrinogenemia have prolonged heavy menstrual bleeding that requires hormonal treatment.15 Paradoxically, patients with afibrinogenemia may have thromboembolic events associated with or without fibrinogen substitution.

Abbreviations: DVT, deep vein thrombosis; TT, thrombin time.
between genotype and phenotype is best documented for some dysfibrinogenemias, including thrombotic-related variants (described below).5

Hypofibrinogenemia is the most rarely reported congenital disorder of fibrinogen. It is associated with symptoms characteristic of both hypofibrinogenemia and dysfibrinogenemia.10 In case of a discrepancy between reduced activity and reduced antigen fibrinogen levels, hypofibrinogenemia should be suspected.5,10 Postpartum hemorrhage and heavy menstrual bleedings are particularly frequent, which is why this subtype of anomaly is most often described in symptomatic women.10,19 The largest literature review published so far, reporting 51 patients diagnosed with hypofibrinogenemia, showed that the cutoff of 0.7 for the ratio of functional concentration of fibrinogen to its antigen level has a diagnostic sensitivity of 86%.19 Interestingly, 22% of patients with hypofibrinogenemia did not show clinical manifestations at diagnosis, while 45% experienced at least 1 benign hemorrhagic event prior to diagnosis, 30% of of bleedings occurred during pregnancy, puerperium, and menstrual disorders.19 Overall, 43% of patients in the studied cohort had at least 1 thromboembolic event with a predominance of venous thrombosis over arterial thrombosis (3:1).16 Spontaneous bleeding associated with fibrinogen abnormalities usually occurs at functional fibrinogen levels of less than 0.7 g/l.8

Classification of congenital fibrinogen disorders

The latest recommendations of the Research Standardization Committee at the International Society on Thrombosis and Haemostasis (ISTH) published in 2018 introduced a new classification of fibrinogen disorders and a modified diagnostic approach to patients with such a suspicion.22 It has been suggested to classify congenital disorders in fibrinogen based on the clinical and biological (fibrinogen activity, antigen, and genotype) phenotype.22 Afibrinogenemia (type 1 congenital fibrinogen disorder):

1. Asymptomatic or bleeding patients are classified as afibrinogenemia (subtype 1A).
2. Patients with concomitant thromboembolic events are classified as afibrinogenemia with phenotypic thrombosis (subtype 1B), even if accompanied by hemorrhagic episodes.

Type 2 includes patients with hypofibrinogenemia classified as:
1. Severe hypofibrinogenemia with a functional fibrinogen concentration of less than 0.5 g/l (subtype 2A)
2. Moderate hypofibrinogenemia with a functional fibrinogen concentration of 0.5 to 0.9 g/l (subtype 2B)
3. Mild hypofibrinogenemia with a functional fibrinogen concentration from 1.0 g/l to the lower limit of the reference range (2C subtype)
4. Familial hypofibrinogenemia with accumulation of fibrinogen in the liver (fibrinogen storage disease), confirmed by histological examination (2D subtype)

Patients with dysfibrinogenemia (type 3 congenital disorder) are distinguished by:
1. Asymptomatic dysfibrinogenemia or dysfibrinogenemia with bleeding tendencies or occasional thrombosis (subtype 3A), for which there is no clear association with the genotype
2. Dysfibrinogenemia associated with thrombosis (subtype 3B) found in patients carrying a known mutation increasing the risk of thrombosis (Fibrinogen Dusart, Caracas V, Jlimuden, New York I, Nijmegen, Melun, and Naples in a homozygous form) or in patients with venous thrombosis or at an early age with a positive family history of thrombosis in first-degree relatives (of the same genotype) with no other known cause of thrombophilia.

The last group of congenital fibrinogen disorders (type 4) includes patients with hypofibrinogenemia classified as:
1. Severe hypofibrinogenemia with fibrinogen antigen of less than 0.5 g/l (subtype 4A)
2. Moderate hypofibrinogenemia with fibrinogen antigen levels between 0.5 and 0.9 g/l (subtype 4B)
3. Mild hypofibrinogenemia with fibrinogen antigen levels from 1.0 g/l to a lower limit of the reference range (subtype 4C)

This recent classification22 did not include patients with an inherited fibrinogen Aα-chain mutation that causes amyloidosis and fibrinogen chain deposition in the kidneys because this fibrinogen variant does not affect routine coagulation screening tests.23

Regardless of the type of the fibrinogen mutation found, it is important to note in all patients: age at diagnosis; the circumstances in which the disease was diagnosed; similar abnormalities or symptoms in the family; and the type of clinical manifestation (hemorrhagic, with major life-threatening bleeding, with recurrent thromboembolic events, or with the need for fibrinogen concentrates).19

Diagnostic workup of congenital fibrinogen disorders Diagnosis of congenital fibrinogen disorders is difficult due to the availability of a vast range of analytical methods and reagents to assess the function of blood coagulation and a large number of mutations in the 3 fibrinogen genes leading to different protein concentrations.4,16 Traditionally, fibrinogen is the only coagulation factor whose potency is expressed in units of concentration (most commonly in clinical practice as g/l), rather than in activity units like other coagulation factors. The measurements of fibrinogen concentrations are standardized. Decreased fibrinogen concentrations should lead to a suspicion of congenital fibrinogen disorders and a further diagnostic evaluation should be performed. Of note, a concentration of fibrinogen, as an acute phase protein, increases in response to inflammatory diseases, infections, nephrotic
syndrome, during pregnancy, during the use of oral hormonal contraceptives, or after surgical interventions, making diagnosis even more challenging and sometimes requiring repeated measurements.1,4

Coagulation tests most commonly used in the diagnostic workup of congenital fibrinogen disorders include: 1) prothrombin time (PT), also automatically expressed in most laboratories as international normalized ratio (INR); 2) activated partial thromboplastin time (APTT); 3) thrombin time (TT); 4) assessment of fibrinogen concentration by the von Clauss method.24

Even a single measurement indicating plasma fibrinogen concentration of less than 1.5 g/l should lead to a more extensive diagnostic workup and, if necessary, genetic testing. The TT assay, which is poorly standardized, has the highest diagnostic sensitivity, although, similarly to PT and APTT, the TT assay has low specificity.25 The measurement of PT, APTT, functional concentration of fibrinogen, and the level of its antigen should constitute the first stage of diagnostic workup in a patient suspected of congenital fibrinogen disorders.22 Determination of the functional concentration of fibrinogen by the von Clauss method is based on the measurement of the coagulation time of poor platelet plasma (by mechanical or optical methods) after activation with high concentration thrombin.26 Antigen levels are usually measured using specific antibodies with detection by immunodiffusion techniques, immunonephelometry, or immunoturbidimetry.26

If the measurement of fibrinogen antigen is not available in a given laboratory, the method of choice should be the determination of fibrinogen concentration based on PT (PT-derived fibrinogen assay).26 PT-derived fibrinogen is an indirect measurement in which the concentration of functional fibrinogen can be estimated on the basis of changes in the optical density of plasma, where the difference in optical density is proportion- al to the concentration of fibrinogen compared with subsequent dilutions of the standard with known concentration of this protein.26 Compared with the von Clauss assay, this method is sensitive to changes in plasma optical density associated with slower fibrinopeptide release and formation of thicker fibrin fibers.26 Therefore, in patients with dysfibrinogenemia, the PT-based measurement of fibrinogen concentrations overestimates its actual concentration 5-fold compared with the von Clauss assay and thus correlates with protein levels measured by immunological methods.24 It is a common practice to use a cutoff of less than 0.7 for the ratio of fibrinogen measured by the von Clauss assay and the antigen or the PT-based method in the diagnosis of dysfibrinogenemia.18 It should be noted that some variants, for example, fibrinogen Longmont (FGG Arg166Cys) or fibrinogen Bordeaux (FGA Arg439Cys), have an apparent decrease in fibrinogen concentration measured using the PT-based method compared with the von Clauss assay.22,27,28

TT and reptilase time in the presence of congenital fibrinogen disorders are often prolonged, but according to the current ISTH guidelines26 they should be considered only as additional tests in patients due to the limited diagnostic value. Indeed, even though TT is commonly used by hematologists as a dysfibrinogenemia screening test, results in the reference range (with prolonged reptilase time), as well as prolonged TT, still require measurement of functional fibrinogen and its antigen level.

Regardless of the diagnostic algorithm, in order to establish the definitive diagnosis of inherited fibrinogen disorders, a detailed analysis of the genes encoding individual fibrinogen chains is necessary. Screening for these abnormalities should be performed in relatives along with the assessment of the relationship between the genotype and the clinical phenotype.22 It is recommended that in quantitative fibrinogen disorders, genetic analysis should start by sequencing FGA (exon 4 and 5), because they often contain mutations associated with protein function loss.24 The next step should be the analysis of less commonly mutated exons (FGA, exon 2; FGB, exons 2 and 6; and FGG, exons 6 and 8) and, if necessary, sequencing of the remaining exons.23 In dysfibrinogenemia, the first stage of the diagnostic workup should be the screening of exon 2 of the FGA gene and exon 8 of the FGG gene.25 Next, exon 5 in FGA, exon 2 in FGB, and exons 3 and 5 in FGG should be assessed.29 However, nowadays, the next-generation sequencing (eg, whole-exome sequencing) is being more cost-effective in identifying a causative mutation in a rare disease. Standard polymerase chain reaction and Sanger sequencing are still useful to confirm the molecular anomaly or for familial studies.

Management of bleeding in congenital fibrinogen disorders Treatment of a- or hypofibrinogenemia and sometimes dysfibrinogenemia is to provide adequate concentrations of functional fibrinogen for proper hemostasis by using freshly frozen plasma (FFP), cryoprecipitate, or plasma-derived fibrinogen concentrate, with the last being the best option.5,14 Cryoprecipitate and FFP are associated with infusion-related adverse reactions, including the risk of fluid overload and transfusion-related acute lung injury as a potentially fatal adverse event.10 In addition, the use of FFP and cryoprecipitate is associated with the supply of large amounts of other proteins such as fibronectin, von Willebrand factor, factor VIII, factor XIII, and macroglobulin.30 Finally, both require thawing, which delays the infusion of the first dose. Clinical studies have shown that the risk of transmitting a pathogen by administering fibrinogen concentrate is negligible.30 Fibrinogen concentrate infusion can be complicated by allergic reactions. The formation of antibodies against this protein have been reported, but without inhibitory effects.31
The patients who require fibrinogen supplementation should be treated by hematologists trained in the management of bleeding disorders. To summarize the key concepts for internal medicine specialists, who may encounter such patients occasionally, it should be highlighted that the therapeutic goal based on expert opinions and observational studies is to achieve a functional fibrinogen concentration (coagulometric method) of 1 to 1.5 g/l. The value of 1 g/l is currently considered the minimal concentration of fibrinogen to maintain the asymptomatic state in most patients, based on publication from the European Network of Rare Hemorrhagic Diatheses; however, some experts suggest a lower target concentration of fibrinogen, that is, 0.5 to 1 g/l. Fibrinogen is administrated either on demand in case of acute bleeding or surgery, or as prophylaxis in patients with afibrinogenemia or severe hypofibrinogenemia to prevent bleeding. Long-term prophylaxis is recommended in patients with afibrinogenemia and major recurrent bleedings, but such strategy can also be considered in primary prophylaxis (ie, before occurrence of first bleeding). Usual infusion strategies, according to the type of product, are indicated below:

1. On demand: fibrinogen concentrate, 50 to 100 mg/kg; cryoprecipitate, 15 to 20 ml/kg; FFP, 15 to 30 ml/kg.
2. As prophylaxis: fibrinogen concentrate, 30 to 100 mg/kg of bw every week; cryoprecipitate, 1 unit 3 times a week or 3 units every 7 to 10 days.

The final dosage should be adjusted individually depending on the frequency of bleedings and their severity. Isolated cases of unsatisfactory hemostasis with recurrent bleeding at fibrinogen concentrations of more than 1 g/l have been reported. Increased fibrinogen clearance is seen during major bleeding, which requires increased fibrinogen concentrate dosage with close monitoring. In case of acute bleeding, it is recommended to administer fibrinogen based at least on daily monitoring. Tranexamic acid can also be administered in the event of minor bleeding or minor surgery planned in patients with hypofibrinogenemia or dysfibrinogenemia with a bleeding phenotype. In women with heavy menstrual bleeding, especially with hypofibrinogenemia, hormonal agents should be considered in addition to oral tranexamic acid during menstrual bleeding.

Management of pregnant women Pregnancy is a high-risk clinical situation in women with congenital fibrinogen disorders, especially in afibrinogenemia. A multidisciplinary approach including an obstetrician, hematologist, and anesthetist, preferably in a hemophilia center, is of key importance, and such women should be referred to a hemophilia center at the first contact with an internist. In women with afibrinogenemia or severe hypofibrinogenemia, fibrinogen infusion should be started as soon as possible. Increased fibrinogen clearance is observed in the third trimester of pregnancy, requiring an increase in the dosage of fibrinogen concentrate with a close monitoring of peak and trough fibrinogen levels. In women with dysfibrinogenemia and history of recurrent miscarriages, fibrinogen supplementation could be considered to achieve a functional concentration of fibrinogen of around 1 g/l. However, such a strategy does not guarantee favorable outcomes and the risk of miscarriage, especially in the first trimester of pregnancy, remains significant. There are no data showing that heparin is still effective after normalization of fibrinogen concentration in dysfibrinogenemia. Postpartum hemorrhage is a frequent complication in women with congenital fibrinogen disorders and should be monitored closely. An increased postpartum thrombotic risk has been reported. An appropriate thromboprophylaxis should be considered in selected women following childbirth.

Management of thrombosis Occurrence of thrombosis in afibrinogenemia is a clinical conundrum. One hypothesis is that the generation of thrombin in a hematoma or during surgery or during pregnancy, without the antithrombin action of fibrin (ie, acting as a trap for circulating thrombin) can lead to strong platelet activation and aggregation stimulated by thrombin and endothelial cell injury, which in turn promotes thrombus formation and thromboembolic events in both the venous and arterial systems. Thrombosis in such patients requires simultaneous supplementation of fibrinogen and administration of anticoagulants, most often heparins, with close clinical supervision and laboratory monitoring. Oral direct thrombin inhibitors and antiplatelet agents, in particular vorapaxar, a protease-activated receptor 1 antagonist, might be considered in afibrinogenemic patients with recurrent arterial thromboses; however, in most countries, these agents are unavailable and their safety remains controversial. Besides the few thrombotic-related dysfibrinogenemic variants, all dysfibrinogenemias can contribute to an increased thrombotic risk. Heparins, precisely low-molecular-weight heparins, for example, enoxaparin, are the drugs of choice in treatment of thrombosis in such patients, as vitamin K antagonists cannot be reliably monitored with INR. The chromogenic assay of factor X could be used to determine the correct INR value on warfarin in patients with dysfibrinogenemia, in whom the INR cannot be accurately determined due to interference with the fibrin endpoint in the INR assays. The duration of anticoagulation depends on the type of thrombosis, the familial history, and the overall phenotype of a patient. In view of this potential thrombotic risk, thromboprophylaxis with heparins should be administrated in all clinical settings with an increased thrombotic risk, in particular during pregnancy and postpartum.

Key points for internists Due to the rarity of congenital fibrinogen disorders, internists are often
In afibrinogenemia and severe hypofibrinogenemia, all new symptoms should be considered as bleeding and treated accordingly until additional investigations are performed.

In afibrinogenemia and severe bleeding, all invasive procedures (including venipuncture) should be avoided and performed only upon approval of hematologist.

Nonsteroidal anti-inflammatory drugs should be avoided in patients with a bleeding phenotype and paracetamol should be preferably used.

Hormonal contraception should be suggested in afibrinogenemic women and severe hypofibrinogenemic women with heavy menses.

Annual visit to a hemophilia center should be organized for all patients with fibrinogen disorders.

Thromboprophylaxis should be considered in patients with dysfibrinogenemia according to recommendations of a given hemophilia center.

Surgical procedure and pregnancy management should be performed under the guidance of specialized centers dealing with bleeding disorders.

not aware of such a condition. Patients in whom reduced fibrinogen concentrations are measured should be referred to hematologists for further workup regardless of the presence or absence of any clinical manifestations to establish a definite diagnosis. Even if patients with severe fibrinogen disorders are treated in hemophilia centers, internists should recognize signs and symptoms that should require an emergency treatment as well as refer patients and their relatives suspected of this type of disorders to specialized centers. Internists and general practitioners should endorse the management in cooperation with the hematologist and treat other diseases, for example, influenza or bacterial infections, in patients with congenital fibrinogen disorders, being knowledgeable about thrombotic or bleeding risk. In terms of the management of pain, internists should be aware of the fact that nonsteroidal anti-inflammatory drugs inhibiting platelet aggregation, for example, aspirin should be avoided in patients with congenital fibrinogen disorders and a bleeding phenotype. Thienopyridines should not be used in such patients either. In asymptomatic fibrinogen disorders, the use of antiplatelet agents following acute myocardial infarction or stroke is initiated and any changes in the therapy should be discussed with a cardiologist and hematologist. On the other hand, thrombosis in patients with congenital fibrinogen disorders, in particular some dysfibrinogenemias, should be effectively managed and reduced fibrinogen concentrations should not lead to a false assumption that patients are at high bleeding risk and anticoagulation should be stopped premature. Such decisions should be discussed with specialists to avoid recurrent thromboembolism. Some general aspects of management and recommendation for internists who take care of patients with congenital fibrinogen disorders are presented in Table 2.

Conclusions  Congenital qualitative and quantitative fibrinogen disorders are rare. A widely available and cheap determination of plasma fibrinogen concentration using a coagulation assay should be considered in patients with bleeding including persistent minor bleeds and heavy menses, in particular when there is a positive family history. Fibrinogen level measurement should be also considered in pregnancy complications and thrombosis without clear risk factors. A patient suspected of having afibrinogenemia, hypofibrinogenemia, or dysfibrinogenemia, with lower fibrinogen concentrations (without obvious acquired cause, for example, disseminated intravascular coagulation or massive acute thrombosis), should be referred to a specialist hematology center for further diagnostic workup including genetic evaluation and family counselling. Proper management is effective in most patients who manifest bleeding related to fibrinogen disorders, therefore search for this abnormality should be encouraged. In Poland, like in many lower-income countries, congenital fibrinogen disorders are underdiagnosed and sparsely reported. Efforts to change this situation should be started from increased awareness of afibrinogenemia, hypofibrinogenemia, or dysfibrinogenemia among general practitioners and internists.
