Short title: Effect of proton pump inhibitor therapy on selected blood parameters.
What’s new?

The study demonstrated that chronic proton pump inhibitor (PPI) therapy may reduce red blood cell count, white blood cell and hemoglobin levels, leading to iron deficiency. It may also affect the concentrations of some micronutrients such as copper and zinc, although the underlying mechanism of this association is not clear. We indicated that a change in gastric pH may not be the only factor affecting the intestinal absorption of trace elements in patients taking PPIs. We hypothesized that their concentrations can be affected also by other factors, such as oxidative stress. On the other hand, gastroprotective effects of PPIs can not only be explained by their antisecretory function. Our findings showed that PPIs should be prescribed with awareness. Monitoring of prolonged therapy should be introduced, particularly in the population of elderly or malnourished patients. This is especially important as PPI are widespread prescribed both in primary care and hospital settings.
Abstract

Introduction Proton pump inhibitors (PPIs) are widely prescribed for several gastrointestinal conditions, often as chronic therapy. The effects of long-term PPI use have not been fully elucidated.

Objectives We aimed to determine the association between chronic PPI use and complete blood count parameters, particularly red blood cell (RBC) count, white blood cell (WBC) count, and hemoglobin concentrations, as well as serum levels of selected micronutrients such as selenium (Se), iron (Fe), copper (Cu), and zinc (Zn).

Patients and methods We enrolled 37 patients on chronic PPI therapy (mean [SD] age, 57.1 [15.4] years) and 30 healthy controls (mean [SD] age, 39.3 [11.8] years). In each group, complete blood count, serum Fe levels were performed, and serum Cu, Zn, and Se levels were measured using atomic absorption spectrometry.

Results RBC and WBC counts were lower in the PPI group compared with controls (mean [SD], 4.24 [0.55] 10^6/µl vs 4.7 [0.4] 10^6/µl, P <0.001 and 6.13 [1.44] 10^3/µl vs 7.3 [1.28] 10^3/µl, P <0.001, respectively]. Hemoglobin and serum Fe concentrations were also lower in the PPI group (mean [SD], 12.5 [1.8] g/dl vs 14.3 [0.8] g/dl; P <0.001 and 16.3 [5.4] µmol/l vs 23.4 [2.7] µmol/l, P <0.001). Serum Zn and Cu concentrations were significantly higher in PPI users than in controls.

Conclusions Chronic PPI therapy may reduce RBC and WBC counts as well as hemoglobin levels, leading to iron deficiency. It may also affect the concentrations of some micronutrients, although the underlying mechanism of this association is not fully clear.

Key words

Complete Blood Count; Copper; Proton Pump Inhibitors; Selenium; Zinc
INTRODUCTION

Proton pump inhibitors (PPIs) are widely prescribed medications for the treatment of acid-related gastrointestinal disorders such as peptic ulcer disease, gastroesophageal reflux disease, or dyspepsia. They also play a role in prevention of gastric ulcers in some clinical situations [1].

The efficacy and perceived safety of PPIs have led to their widespread prescription and over-the-counter availability. PPIs are on the top of overprescribed medications for United States adults [2]. PPIs should only be used when appropriate, in accordance with label instructions and for the shortest duration of time to achieve symptom response but several reports so far have described inappropriate prescription of PPIs both in primary care and hospital settings [1,3]. Prolonged PPI therapy is associated with adverse events and pharmacologic interactions [3,4,5]. Undesirable effects include small intestinal bacterial overgrowth, hypomagnesemia, decreased cyanocobalamin absorption, acute interstitial nephritis, bone fractures, and Clostridium difficile-associated diarrhea [6]. The use of PPI increases mortality and hepatic decompensation in patients with liver cirrhosis [5]. A correlation between PPI use and cognitive function has been postulated, but the exact effect seems to be unclear [7]. A number of studies indicated a possible effect of changes in gastric acidity on the level of micronutrients, such as selenium (Se), zinc (Zn), and copper (Cu).

Selenium is an essential micronutrient that is incorporated in a variety of selenoproteins to render their beneficial physiologic functions. It also plays an important role as an antioxidant and is considered an anticancer nutrient [8]. Steevens et al [9] reported a negative correlation between the Se status and gastric and esophageal cancers.

Zinc is another micronutrient with a pivotal role in homeostasis, immune function, oxidative reactions, apoptosis, and aging. It is a structural element of Cu-Zn superoxide dismutase, which is intracellularly distributed in red blood cells (RBCs); therefore, it is involved in
oxidative reactions. Zinc deficiency is related to several conditions such as malignancies, neuropsychiatric disorders, autoimmune diseases, or aging processes with apoptosis [10]. Copper is an essential trace element in human physiology and a major constituent of numerous enzymes. It is a potent antioxidant that plays an important role in the oxidant defense system [11]. Its deficiency results in microcytic anemia, leukopenia, and reduced bone density [12].

The aim of this study was to determine the effect of PPIs on complete blood count parameters, particularly RBCs, white blood cells (WBCs), and hemoglobin (Hb) concentrations. Moreover, we measured the serum levels of Se, iron (Fe), Cu, and Zn in PPI users in comparison with nonusers (controls).

**PATIENTS AND METHODS**

*Study population*

A total of 67 participants were enrolled to the study, including 37 PPI users (55%) and 30 healthy controls (45%) who did not use PPIs. The mean (SD) age of PPI users was 57.1 (15.4) years, and of controls, 39.3 (11.8) years. In the PPI group, 18 patients used pantoprazole; 7, omeprazole; 1, lansoprazole; 9, esomeprazole; and 2, dexlansoprazole. Enrolled patients used the PPI due to gastroesophageal reflux disease and functional dyspepsia. The time of PPI intake varied between 3 and 10 years at the moment of referral to Outpatient Gastroenterology and Hepatology Clinic at Jagiellonian University Medical College in Kraków, Poland. Periods without drug use did not exceed 3 months.

The exclusion criteria were as follows: pregnancy, any malignancies, diabetes mellitus, obesity (body mass index ≥30 kg/m²), cardiovascular diseases (hypertension, coronary artery disease, valvular heart disease, cardiac arrhythmias), tobacco smoking, intake of medications that may affect serum Se, Zn, or Cu concentrations, as well as malabsorption syndromes (eg, celiac disease, short bowel syndrome). Included patients did not present overt or occult
bleeding symptoms. They did not take medications such as nonsteroidal anti-inflammatory drugs, steroids, anticoagulant therapy, immunosuppressive, antiviral drugs, selective serotonin reuptake inhibitor treatment and chemotherapy.

Biochemical studies

The biochemical analyses including complete blood count and the measurement of serum Fe concentrations were conducted at the Biochemical and Molecular Diagnostics Unit of the Department of Clinical Biochemistry at Jagiellonian University Medical College. Complete blood count included the measurement of Hb concentrations, mean corpuscular volume (MCV), WBC, RBC, platelet count, and red blood cell distribution width (RDW).

The serum levels of Cu and Zn were measured with a Perkin-Elmer 5100 ZL atomic absorption spectrometer (PerkinElmer, Inc., Norwalk, CT, USA) using flame technique. The calibration curves for Cu and Zn were performed using 0.00, 0.25, 0.50, 1.00, 2.00, and 3.00 mg·l⁻¹ standards. These solutions were prepared by dilution of certified standard solutions, 1000 mg·l⁻¹ Merck, Darmstadt, Germany: Cu – 1.19786.0500 and Zn – 1.19806.0500.

Defrosted serum (0.5 ml) was mixed with 2 ml of demineralized water (Millipore RQ10, Vienna, Austria) and analyzed as described above. Each sample was measured 3 times. If the relative standard deviation of the 3 measurements exceeded 5%, then the sample was re-measured. The correctness of the obtained results was checked with Seronorm™ (200805) and Pathonorm™ (100705) control serum (Sero, Billingstad, Norway). The parameters of the Cu and Zn analysis were as follows: 1) for Cu – wavelength, 324.8 nm; lamp current, 15 mA; slit width, 0.7 nm; air flow, 9.0 l·min⁻¹; and acetylene, 2 l·min⁻¹; and 2) for Zn – wavelength, 213.9 nm; lamp current, 18 mA; slit width, 0.7 nm; air flow, 10.8 l·min⁻¹; and acetylene 2 l·min⁻¹.
The Se level was determined using an Agilent Technologies 240Z AA atomic absorption spectrometer (Agilent Technologies, Santa Clara, CA, USA) with graphite furnace atomization and Zeeman background correction. The calibration curve was prepared using 3 serum standards containing 0.35, 0.61, and 1.77 μmol·L⁻¹ Se. The accuracy of the results was confirmed with Seronorm™ reference material (Trace Elements Serum L-1, Sero). As a light source, a hollow-cathode lamp with enhanced light intensity (“ultra-lamp”); as an inert gas, high-purity argon (99.998%) was used.

Serum samples were mixed with 0.1% Triton solution (150 μl + 100 μl) to improve homogeneity. Owing to the presence of complex organic matrix in the samples, a chemical modifier was used and air-assisted ashing was included in the temperature program of the graphite furnace. The samples were measured in duplicates unless the obtained precision was not satisfactory (in such case samples were re-measured). The parameters of the analysis were as follows: wavelength, 196.0 nm; lamp current, 12 mA; slit, 1.0 nm; chemical modifier, 5% HNO₃ containing 1500 mg·L⁻¹ Pd and 6000 mg·L⁻¹ Mg(NO₃)₂; air-assisted ashing temperature, 400°C; inert-gas ashing temperature, 1150°C; and atomization temperature, 2600°C.

Ethical approval

The study protocol was approved by the Local Bioethics Committee at Jagiellonian University (decision no. KBET 122.6120.86.2015/ as of May 28, 2015). All participants gave their written informed consent to be included in the study.

Statistical analysis

Data were expressed as mean (SD). The differences between groups were tested using the Student t test or Welch test, as appropriate. The Levene test was used to assess the equality of variances in the study groups. A P value of less than 0.05 was considered significant. Pearson
correlation coefficients were calculated for pairs of parameters. A partial least square model (PLS) was applied to describe the correlation structure between parameters in a mixed group of controls and patients treated with PPIs (using the analysis of component weights) and to reveal possible differences between controls and patients (using the analysis of PLS score plot). The PLS model showed the correlations between predictive parameters such as age of patients, blood parameters, and concentrations of trace elements, with response parameters including Fe and Hb concentrations (parameters characterizing oxygen binding and transport). The parameters with large weights (>0.3) in the PLS model were assumed to be correlated with one another. To express the strength of bivariate associations, for the pairs of correlated parameters, the algebraic products of their corresponding weights and cosine of the corresponding angle were calculated (these coefficients are called the correlation weights). The “corresponding angle” was defined as the angle determined by 2 lines connecting the origin with coordinates of both parameters on the PLS weights plot. The PLS approach was also applied with the aim to identify any possible clusters of patients and healthy controls in the PLS score plot. Statistical analyses were carried out using the STATISTICA v.12 package (Statsoft, Tulsa, Oklahoma, United States) and SIMCA-P v.9 (Umetrics, Umeå, Sweden). The software delivered by MP System Co. (Chrzanów, Poland) was used to calculate correlation weights for the pairs of parameters in the PLS model and to detect outliers.

RESULTS

The comparison of analyzed parameters between the PPI and control groups is shown in Table 1. Patients treated with PPIs had significantly lower RBC and WBC counts as well as serum Fe levels than controls. The Hb level was also significantly lower in patients treated with PPIs. There was no difference in platelet counts between groups. Serum Zn and Cu levels were lower in controls than in the PPI group, but no differences were observed for Se
levels. The Pearson correlation analysis showed positive correlations between RBC and Hb levels, as well as RBC and serum Fe levels (Table 2). An increase in the RBC count was correlated with higher Hb concentrations and MCV. There was also a positive correlation between serum Se levels and MCV. No significant correlations between RBC and Cu or Se levels were observed (Table 2).

Correlation weights obtained from the PLS model are presented in Table 2. The final PLS model with 2 significant components, according to cross-validation, explained 50.6% of variance in the predictive parameters, and 38.6% of variance in the response parameters, with eigenvalues of 1.79 and 1.24 for the first and second components, respectively. Five predictive parameters (age, Cu, Se, MCV, and WBC) and 2 response parameters (Fe, Hb) were included in the PLS model, while others were excluded as they were considered noninformative (Figure 1). The first latent component in this model had positive weights predominantly for the RBC count, as well as for Hb and Fe levels, while it had high negative weight for age. The highest positive correlation weights based on this latent component were revealed between RBC count and both Hb and Fe levels. The second latent component was loaded again mainly by RBC count, and 4 other parameters with similar weights: Hb, Se, MCV, and Cu. Therefore, RBC count had high correlation weights with all these parameters. The PLS model revealed correlation structure between the above parameters: RBC and Hb, RBC and Fe, Se, and MCV, and also between RBC and Se, RBC and Cu, age and Hb, as well as age and RBC. For the correlation between RBC count and MCV, we obtained discrepant results using the PLS model and Pearson correlation analysis.

The scatter of patients in space determined by the first 2 latent components is shown in Figure 2. A relatively tight cluster of squares representing controls can be distinguished among the cloud of dots representing patients. True positive and negative rates for this cluster were 86.7% and 87.8%, respectively. The separation between this cluster and patients was evident
in the direction determined only by the first latent component of the PLS model. Considering this result, controls within this cluster were characterized by apparently higher RBC, WBC, Hb, and Fe levels, as well as lower Cu levels and age compared with patients. This is in line with the results obtained by the Student t test or Welch test (Table 1).

**DISCUSSION**

The effect of prolonged PPI use on complete blood count has not been fully elucidated so far. Our results revealed a relationship between prolonged PPI use and reduced RBC and WBC counts as well as Hb levels. One of the reasons for this finding may be reduced Fe levels demonstrated in patients treated with PPIs in comparison with controls, as reduced Fe levels may lead to subsequent changes in other parameters. In addition, we showed an effect of PPIs use on the serum concentrations of Cu and Zn.

Data on suppression of gastric acid during long-term PPI therapy leading to iron-deficiency anemia are sparse. Patients with Zollinger-Ellison syndrome during such therapy were shown to have reduced Fe levels [13]. On the other hand, Hutchson et al [14] showed reduced frequency of phlebotomy and absorption of nondietary Fe in patients with hereditary hemochromatosis on prolonged PPI therapy. In a retrospective cohort study, Sarzynski et al [15] reported a decrease in Hb, Ht, and MCV levels among patients on PPI therapy. Moreover, in a case-control study, Lam et al [16] reported that a PPI use longer than 2 years was associated with iron-deficiency anemia. In an open-labelled study, Qorray-Bytygi et al [17] assessed ferritin levels at the beginning and after 12 months of PPI therapy. They reported lower ferritin levels at 1 year in comparison with controls.

The presence of gastric acid facilitates dietary Fe absorption by dissociating Fe salts, increasing solubility, and transforming them to the ferrous form [18]. These above
observations are consistent with the results of our studies indicating decreased RBC count as well as Hb and Fe level in PPI users. The PLS model revealed correlation structure between the majority of analyzed parameters. The RBC count was strongly correlated with all parameters except the WBC count. The biochemical basis for the observed correlations between RBC and Hb, Fe, and Cu can be easily explained, because Fe and Cu play a fundamental role in erythropoiesis, and Hb is an essential constituent of RBCs. The negative correlation of age with RBC and Hb may be explained by the fact that lower RBC count and Hb levels were observed in patients who were, at the same time, older than controls. The question of whether this was an accidental finding or whether it occurred in the course of the disease or due to the disease itself needs to be addressed in future studies.

The distinct cluster of squares representing controls (containing only a few patients) on the plane defined by the first 2 latent components of the PLS model reflects a notable difference in biochemical characteristics between patients and controls, which means that the PLS model is effective enough to differentiate between these 2 groups. Our analysis indicated that RBC, Hb, and age were the parameters that differed the most between patients and controls. To the best of our knowledge, no clinical trials on patients taking PPIs have used the PLS approach to interpret the results.

A drawback of this study is a relatively small number of patients studies and quite a big difference in mean age with control and treatment group. To exclude additional effects on blood test and iron values, included patients did not present overt or occult bleeding symptoms. The study group, despite being older than the control group, did not have more serious, chronic diseases that could affect the parameters tested, did not take medications such as nonsteroidal anti-inflammatory drugs, steroids, clopidogrel. We tried to eliminate the
influence of the age difference of the studied groups on the results of measured parameters by using the partial least square model.

In contrast to the RBC count, we did not observe any significant differences in platelet count between groups. Literature data concerning platelet count are conflicting. Only a few case reports and one retrospective study described PPI-induced thrombocytopenia [19-22].

To our best knowledge, there have been no studies analyzing the WBC count during PPI therapy. Neutropenia and agranulocytosis are rare adverse effects associated with PPI treatment. So far, only a few case reports of severe neutropenia or agranulocytosis during PPI use (ie, omeprazole) have been published [23-25].

The suggested pathomechanism of neutropenia includes immune reactions and cross-reactivity. Also synergic reactions with other potential causes of neutropenia should be considered. In our study, we observed a significantly lower WBC count in patients on PPI than in controls, and only 2 patients had slight leukopenia. Further studies in patients on PPI therapy, with careful monitoring of WBC and its subpopulations, are needed.

It has been shown that gastric acid is required for the release of vitamin B\textsubscript{12} from food; therefore, PPIs are believed to cause vitamin B\textsubscript{12} deficiency. In our study, we did not measure serum vitamin B\textsubscript{12} concentrations. However, in a cross-sectional study, den Elzen et al [26] reported that long-term PPI use was not associated with vitamin B\textsubscript{12} deficiency. On the other hand, Qorraj-Bytyqi et al [17] reported a change in serum cyanocobalamin concentrations at 1 year of PPI therapy.

To the best of our knowledge, there are no literature data on changes in MCV during PPI therapy. Despite significant differences in Fe levels between patients on PPI and controls, we did not observe any differences in MCV. This finding can be explained by the multifactorial effect of various parameters on the size of erythrocytes. The values of MCV may be affected by Fe deficiency and vitamin B\textsubscript{12} deficiency. An interesting observation is the positive
The correlation between Se levels and MCV, as well as the surprising lack of significant differences in these parameters between study groups. This relationship requires further research. The high concentration of Se in RBCs (higher than in most other blood fractions or whole blood) [27], high activity of selenoenzyme glutathione peroxidase [28] as well as Se transfer to and from Hb [29] have been already reported by various authors. However, the molecular mechanisms behind the positive correlation between plasma Se levels and RBC count remain to be fully clarified. Of note, Wasowicz and Zachara [30] found a correlation between Se levels in erythrocytes and whole blood ($r = 0.879$, $P < 0.001$).

Hypochlorhydria may contribute to decreased calcium and magnesium absorption and could have the same effect on other cations, such as Zn [1]. It should be noted that plasma Zn levels are not affected by mild changes in dietary Zn, and only a significant and prolonged reduction of Zn intake leads to a notable deficiency [31]. Some publication reported inhibited absorption of Zn during PPI therapy [32]. On the other hand, Turnbull et al [33] indicated that low gastric pH may not be necessary for intestinal absorption of Zn. Serfaty-Lacrosniere et al [34] did not find a significant difference in intestinal Zn absorption between omeprazole-treated patients and controls. These observations seem to be in line with the results of our study. Surprisingly, we showed higher serum Zn concentrations in PPI-treated group than in controls. Moreover, Ergul et al [35] showed a negative correlation between vitamin B$_{12}$ levels and Zn deficiency. This suggests that Zn absorption may be a more complex issue than it has been considered so far. Importantly, Kirchoff et al [36] indicated that Zn results in a rapid and prolonged reduction of gastric acid production. Perhaps the observed increase in Zn concentrations in the PPI group may be a manifestation of defense mechanisms in conditions associated with hypersecretion of acid regardless of PPI treatment.

The adverse consequence of Zn excess is Cu depletion [32]. A reduction in Cu levels may lead to anemia, nerve damage, and bone loss [37]. There are scarce and conflicting data on the
effects of PPIs on Cu levels. Plantone et al [38] hypothesized that a chronic and prolonged reduction of gastric acidity may reduce Cu absorption. Joshaghani et al [39] showed no significant difference in serum Cu concentrations after 8 weeks of omeprazole use. On the other hand, Ece et al [40] found that while Hb values of children with iron-deficiency anemia were decreasing, their serum Cu concentration were increasing. Thus, an increase in Cu absorption occurs with increasing Fe deficiency. This is in line with our observations. Patients on PPI therapy in our study showed higher serum Cu levels and lower Fe levels in comparison with controls. Moreover, Cu and Zn levels in the PPI group were significantly higher than in controls. This may indicate that a change in gastric pH may not be the only factor affecting the intestinal absorption of trace elements.

Selenium plays a major role in redox reactions and controls cell-mediated immunity [41]. Selenoproteins determine a protective mechanism against reactive oxygen and nitrogen species. High levels of this micronutrient may have a negative effect on carcinogenesis [42]. Nezhad et al [43] reported higher Se levels in patients with functional dyspepsia in comparison with those with gastric cancer. Ustundag et al [44] reported that Se collected in gastric tissue in patients with *Helicobacter pylori* (*H. pylori*)-related antral inflammation and then its levels significantly decreased after effective *H. pylori* eradication. Wu et al [45] also reported a reduction in serum Se levels after *H. pylori* eradication. To our knowledge, there are currently no reports of the PPI impact on Se status. The changes of microbiota in the small intestine because of prolonged PPI treatment may play an important role in regulation of serum Se levels, because it is mostly absorbed in the duodenum and cecum by active transport through a sodium pump [46]. Despite this, we found no significant difference in Se concentrations between our study groups.

PPIs may interact with other drugs by reducing gastric acidity, by modifying metabolism (generally through the cytochrome P450 (CYP) enzyme system), or by inhibiting extragastric
renal proton pumps [47]. In order to exclude of these potential interactions, patients with serious concomitant medical conditions requiring use of immunosuppressive, antiviral, selective serotonin reuptake inhibitor treatment or chemotherapy were excluded from the study.

It is considered that intermittent over-the-counter PPI use would not be expected to have any deleterious effect on absorption of micronutrients such as iron, calcium, magnesium, and vitamin B12 [47], however prescription PPIs in our study were generally administered at higher doses and the durations of treatment were longer.

Our results may indicate that the concentrations of micronutrients such as Zn, Se, or Cu in patients taking PPIs are not only dependent on their absorption potentially impaired due to the reduction of gastric acidity. We hypothesize that their concentrations can be affected also by other factors, such as oxidative stress. All the above trace elements are potent antioxidants involved in the oxidant defense system. On the other hand, gastroprotective effects of PPIs cannot only be explained by their antisecretory function. Recent studies have shown a more direct effect of omeprazole on the integrity of gastric mucosa, including antiapoptotic, anti-inflammatory, and free radical scavenging functions [48]. Because the emerging evidence indicates an involvement of reactive oxygen species in the pathomechanism of gastric lesions [48], the antioxidant actions of PPIs might produce the noted acid-independent gastroprotective effects. Becker et al [49] demonstrated that heme oxygenase-1 is an antioxidant mediator of PPIs in gastric epithelial cells as well as vascular endothelial cells.

High-dose PPIs have shown promise as chemopreventive agents for esophageal adenocarcinoma in Barrett esophagus fitting with the hypothesis that this cancer is an inflammatory-mediated malignant response to prolonged acid exposure [50]. The involvement of Zn, Se, and Cu in a potential antioxidant reaction induced by PPI requires further research.
Conclusions

Our findings show that PPIs should be prescribed with caution and awareness. Prolonged PPI use affects complete blood count, in particular RBCs and WBCs. Moreover, PPIs cause changes in iron absorption, with subsequent changes in RBC count and Hb levels. Monitoring of prolonged therapy should be introduced, particularly in the population of elderly or malnourished patients. Inappropriate PPI may result in significant side effects and potential interactions. Awareness of evidence-based guidelines and targeted medicine prescription strategies are essential for cost-effective and safe use of this drug class. Patients overusing PPIs should be screened and properly educated about guideline recommendations and indications for prescription.

The concentrations of some micronutrients may change as a result of PPI use, although the mechanism of this phenomenon is complex and not fully clear. The antioxidant functions of PPIs might account for the noted acid-independent gastroprotective effects. The involvement of Zn, Se, and Cu in a potential antioxidant reaction induced by PPI requires further research. Comparative studies on the concentrations of these micronutrients before and after the PPI therapy are needed. Further research with higher number of enrolled subjects with a uniform distribution of age between the groups to support our preliminary observations are necessary.

Data are presented as mean (SD).

Abbreviations: Cu, copper; Fe, iron; Hb, hemoglobin; MCV, mean corpuscular volume; NS, nonsignificant; PPI, proton pump inhibitor; RBC, red blood cells; RDW-CV, red blood cell distribution width, coefficient of variation; RDW-SD, red blood cell distribution width, standard deviation; Se, selenium; WBC, white blood cells; Zn, zinc
Table 2. Correlation weights based on the partial least square model (only correlation weights with absolute values higher than 0.15 are shown)

Abbreviations: see Table 1
Figure 1. The weights of the first 2 components of the partial least square model. The dots represent predictor parameters, while the triangles represent response parameters.

Abbreviations: see Table 1.

Figure 2. The projection of subjects on the plane defined by the first 2 latent components of the partial least square model. The elliptical shape represents the cluster of controls.
